

Homeostasis is the maintenance of the steady state of equilibrium in the internal environment of an animal. An animal needs to maintain a constant internal environment, despite fluctuations by internal or external influences, to ensure the animal's survival and ability to reproduce. Osmoregulation is an example of homeostasis. It is way osmosis is controlled by the animal to maintain a water balance. Osmosis is the net movement of water molecules from an area of high concentration to an area of low concentration. ①

Euryhaline fishes live in a habitat surrounded by water and their body contains a high percentage of water. They live in both fresh water and salt water during their lives. They are born in in fresh water and migrate out to marine waters for most of their life. They return to the place they were born in fresh water to spawn. Changing between these two water environments can cause rapid changes in the balance of water in their body. There is a need to create and maintain a stable osmotic balance of water and salts. An example of euryhaline fishes is the Chinook salmon (*Oncorhynchus tshawytscha*). They are adapted to the changes they face in their lifetime through the control system of osmoregulation. ①

Osmoregulation is an example of a negative feedback, homeostatic control system. This system detects changes in the salinity of the water Chinook salmon live in, working to keep the body water concentration constant. The osmoregulatory feedback mechanism works differently when they are in fresh water and marine environments. Like all negative feedback systems it consists of components which detect the change, and then employs a process to negate the change. There are five components in the negative feedback system (see diagram below): the **stimulus** and its variability, the **receptor**, the **control centre** and the **effector**. The stimulus is basically an action or condition which accelerates the fish's physiological response. In this case it is the change in water salinity or salt level within the body of the euryhaline fish, and the response to it would be by reversing the effect. The change in the environment is detected by the receptor. In these fish, the receptor is the hypothalamus which is part of the brain. The hypothalamus detects how concentrated the blood is inside the fish, i.e. if there are too many or too few water molecules. The hypothalamus also stimulates the pituitary gland next to it, which is the control centre. The role of the control centre is to determine the appropriate outcome for the stimulus, which is to reverse the change in the water salinity in the fish. The effector includes the kidneys and gills, which respond to the commands set by the pituitary gland to oppose the stimulus. ②

When the euryhaline fish is in salt water environments there are more water molecules inside the body cells than outside the body cells. Therefore due to osmosis, the water molecules move out of the body cells. Osmoreceptors in the hypothalamus detect that there is a high concentration of salts in the blood, and stimulate the pituitary glands to release the hormone cortisol into the bloodstream. This regulates plasma ions causing the transport activity of ions to take place within the gill cells - the main site for the transport of sodium and chloride ions. The gills contain epithelial cells which are specialised to remove  $\text{Na}^+$  and  $\text{Cl}^-$  ions by one of two ways: active or facilitated transport. Active transport is when substances move against their concentration gradient. Facilitated transport involves channels in the membrane that ions and larger molecules cannot diffuse through. ③

- 3 The kidney removes other salts such as  $Mg^{2+}$  and  $SO_4^{2-}$  by passive diffusion through their urine, which is quite concentrated due to the ion loss. The concentrated urine is also due to the increase in ADH hormone which is released by the pituitary gland, and carried to the kidney by blood. ADH causes more water to be reabsorbed by the kidneys.
- When the euryhaline fish is in a fresh water environment, there are more water molecules outside their body cells than inside their body cells. Therefore due to osmosis, the water molecules move inside the body cells. Osmoreceptors in the hypothalamus detect the high concentration of water within the blood to stimulate the pituitary glands to release the hormone Prolactin into the bloodstream. The hormone causes the transport activity of ions to take place within the epithelial gill cells while they actively absorb salts across the gill epithelium. The gills contain special ion pumps which exchange  $Na^+$  and  $Cl^-$  ions for  $NH_4^+$  and  $HCO_3^-$  ions across the gill membrane against the concentration gradient.

There are various things that can lead to disruptions in the control system, such as water-borne toxicants which fish gills are sensitive to; for example, organic pollutants, toxicants and micro-organisms. Toxicants such as copper and other heavy metals can damage the gill membrane by interrupting the ion transport mechanism within chloride cells, by increasing the permeability of the gill epithelium to water molecules and ions. This can increase the movement of ions across gills more than normal. Excessive loss of water molecules can cause dehydration within the fish which can ultimately result in death. Reactions within the fish's body like any other living thing can only happen if the right pH, salt level and nutrients are maintained.
